1 The Math

Going deeper into Number Theory has helped in building concepts very fundamentally (even some which are not currently needed). Of all I've read in [3] the topics I've found interesting is the studies involved in trying to find out the pattern of distribution of primes.

1.1 Primes

There is a clever way of identifying all primes lesser than a given integer n , *THE SIEVE OF ERATOSTHENES*. It works by picking up primes in line and eliminating it's multiples from the list till the prime is less than or equal to \sqrt{n} , leaving us with primes in the list.

Euclid proof that there exists infinite number of primes and the involved proving techniques turns out very important. For example, the theorem

$$\text{If } p_n \text{ is the } n^{\text{th}} \text{ prime, then } p_n \leq 2^{2^{n-1}}$$

bounds primes using the Euclidean numbers and Induction.

1.2 Congruence

The notations and properties of Congruence turns out to be of massive importance to Cryptography. The Definition of Congruence goes like this:

Let n be a fixed positive integer. Two integers a and b are said to be *congruent modulo n* , symbolised by

$$a \equiv b \pmod{n}$$

if n divides the difference $a - b$; that is, provided that $a - b = kn$ for some integer k .

It's comes with some interesting properties:

Theorem 4.2. Let $n > 1$ be fixed and a, b, c, d be arbitrary integers. Then the following properties hold:

- (a) $a \equiv a \pmod{n}$.
- (b) If $a \equiv b \pmod{n}$, then $b \equiv a \pmod{n}$.
- (c) If $a \equiv b \pmod{n}$ and $b \equiv c \pmod{n}$, then $a \equiv c \pmod{n}$.
- (d) If $a \equiv b \pmod{n}$ and $c \equiv d \pmod{n}$, then $a + c \equiv b + d \pmod{n}$ and $ac \equiv bd \pmod{n}$.
- (e) If $a \equiv b \pmod{n}$, then $a + c \equiv b + c \pmod{n}$ and $ac \equiv bc \pmod{n}$.
- (f) If $a \equiv b \pmod{n}$, then $a^k \equiv b^k \pmod{n}$ for any positive integer k .

Figure 1: Some properties with Congruence [2]

1.3 Other Things

Except these, history leads to various interesting theorems and concepts. Namely, Fermat's Theorem, *pseudoprimes* (n such that $n|2^n - 2$), Wilson's Theorem and Number-Theoretic functions.

2 Introduction to Cryptography

2.1 Terminology

Cryptography : (from the Greek *kryptos* meaning hidden and *graphein* meaning to write)
The science of making communications unintelligible to all except authorized parties.

Plaintext : The information to be concealed

Ciphertext : The code

Encrypting : The process of converting plaintext to ciphertext

Decrypting : The process of converting ciphertext to plaintext

Cryptanalysis : Study of techniques used for deciphering a message without any knowledge of the enciphering. Cryptanalysis is what the layperson calls "breaking the code."

Brute-Force Attack It involves trying every possible key until an intelligible translation of the ciphertext into plaintext is obtained

2.2 Historical Ciphers

2.2.1 Caesar Cipher

This method was used by the great Roman Emperor Julius Caesar around 50 B.C..

It's a rudimentary substitution cipher in which each letter of the alphabet is replaced by the letter that occurs three places down the alphabet, with the last three letters cycled back to the first three letters.

If P is the digital equivalent of a plaintext letter and C is the digital equivalent of the corresponding ciphertext letter, then

$$C \equiv P + 3 \pmod{26}$$

For example, a Caesar cipher for

CAESER WAS GREAT

is

FDHVDU ZDV JUHDW

A	B	C	D	E	F	G	H	I	J	K	L	M
00	01	02	03	04	05	06	07	08	09	10	11	12
N	O	P	Q	R	S	T	U	V	W	X	Y	Z
13	14	15	16	17	18	19	20	21	22	23	24	25

Figure 2: An example of correspondence between letters and digits in Caesar Cipher [1]

Such Encryption schemes in which the original message is replaced by the same cipher substitute are called *monoalphabetic ciphers*. These schemes turn out to be vulnerable as they can be easily decrypted using frequency analysis. The frequency analysis works by comparing the relative frequency of letters with a standard frequency distribution for English. Further, instead of single letters, a block of two or more letters can also be analysed such way. If the message is long enough, this technique might be sufficient.

2.3 Polyalphabetic Ciphers

In such schemes, a plaintext letter has more than one ciphertext equivalents depending on its position in the message.

A famous example of this scheme is given by a French cryptographer **Blaise de Vigenere** (1523-1596). To implement this system, the communicating parties agree on an easily remembered word or phrase. With the standard alphabet numbered from $A = 00$ to $Z = 25$, the digital equivalent of the keyword is repeated as many times as necessary beneath that of the plaintext message. The message is then enciphered by adding, modulo 26, each plaintext number to the one immediately beneath it. The process may be illustrated with the keyword READY, whose numerical version is 17 04 00 03 24. Repetitions of this sequence are arranged below the numerical plaintext of the message

ATTACK AT ONCE

to produce the array

00	19	19	00	02	10	00	19	14	13	02	04
17	04	00	03	24	17	04	00	03	24	17	04

When the columns are added modulo 26, the plaintext message is encrypted as

17 23 19 03 00 01 04 19 17 11 19 08

or, converted to letters,

RXTDAB ET RLTI

A weakness in Vigenere's approach is that once the length of the keyword has been determined, a coded message can be regarded as a number of separate monoalphabetic ciphers, each subject to straightforward frequency analysis.

A clever modification that Vigenere contrived for his polyalphabetic cipher is currently called the *autokey* ("automatic key"). This approach makes use of the plaintext message itself in constructing the encryption key. The idea is to start off the keyword with a short seed or primer (generally a single letter) followed by the plaintext, whose ending is truncated by the length of the seed. For example, assume that the message

ONE IF BY DAWN

is to be encrypted. Taking the letter K as the seed, the keyword becomes

KONEIFBYDAW

When both the plaintext and keyword are converted to numerical form, we obtain the array

14 13 04 08 05 01 24 03 00 22 13
10 14 13 04 08 05 01 24 03 00 22

Adding the integers in matching positions modulo 26 yields the ciphertext

24 01 17 12 13 06 25 01 03 22 09

or, changing back to letters:

YBR MN GZ BDWJ

A way to ensure greater security in alphabetic substitution ciphers was devised in 1929 by **Lester Hill**, an assistant professor of mathematics at Hunter College. Briefly, Hill's approach is to divide the plaintext message into blocks of n letters (possibly filling out the last block by adding "dummy" letters such as X's) and then to encrypt block by block using a system of n linear congruences in n variables.

In its simplest form, when $n = 2$, the procedure takes two successive letters and transforms their numerical equivalents P_1P_2 into a block C_1C_2 of ciphertext numbers via the pair of congruences

$$\begin{aligned} C_1 &\equiv aP_1 + bP_2 \pmod{26} \\ C_2 &\equiv cP_1 + dP_2 \pmod{26} \end{aligned}$$

To permit decipherment, the four coefficients a, b, c, d must be selected so the $\gcd(ad - bc, 26) = 1$.

In general terms, the Hill system can be expressed as

$$\begin{aligned} C &= E(K, P) = PK \pmod{26} \\ P &= D(K, C) = CK^{-1} \pmod{26} = PKK^{-1} = P \end{aligned}$$

where

P is the vector of plaintext letters in a block,
 C is the vector of ciphertext letters in a block,
 K is the Key,
 E is the encryption scheme, and
 D is the decryption scheme

However, the key can be easily found if some plaintext-ciphertext pair is known in a message.

2.4 Vernam's Cipher

An influential nonalphabetic cipher was devised by Gilbert S. Vernam in 1917 while he was employed by the American Telephone and Telegraph Company (AT&T). Vernam was interested in safeguarding information sent by the newly developed teletypewriter in which each letter was represented as a five digit binary code.

Any plaintext message such as

ACT NOW

would first be transformed into a sequence of binary digits:

110000111000001001100001111001

Vernam's innovation was to take as the encryption key an arbitrary sequence of 1's and 0's with length the same as that of the numerical plaintext. A typical key might appear as

101001011100100010001111001011

where the digits could be chosen by flipping a coin with heads as 1 and tails as 0.

Finally, the ciphertext is formed by adding modulo 2 the digits in equivalent places in the two binary strings.

The result in this instance becomes

01100110010010101110111110010

A crucial point is that the intended recipient must possess in advance the encryption key, for then the numerical plaintext can be reconstructed by merely adding modulo 2 corresponding digits of the encryption key and ciphertext.

Note: *In the early applications of Vernam's telegraph cipher, the keys were written on numbered sheets of paper and then bound into pads held by both correspondents. A sheet was torn out and destroyed after its key had been used just once. For this reason, the Vernam enciphering procedure soon became known as the one-time system or one-time pad.*

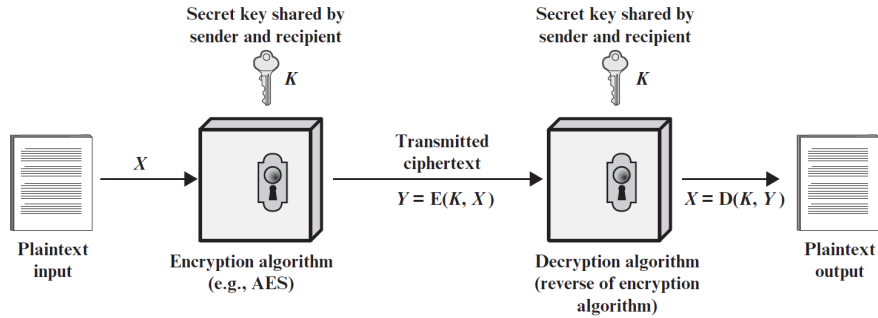

Figure 3: Simple Illustration of Symmetric Encryption [4]

3 Symmetric Key Cryptography

All Historical Ciphers mentioned have Symmetric Encryption scheme. This scheme focuses solely on having a single key for encryption and decryption of the message.

3.1 Playfair Cipher

The best-known multiple-letter encryption cipher is the Playfair, which treats digrams (frequency of two-letter combinations) in the plaintext as single units and translates these units into ciphertext digrams.

The working of this technique is illustrated by an example in [5]: Figure 4 Nevertheless it uses a stronger encryption scheme than Caser Cipher, it keeps the structure of the message simple enough for a cryptanalyst to tackle down, which can be done by tracking the relative frequencies of letters.

The techniques discussed above so far involve substitution of a ciphertext symbol for a plaintext symbol. A very different kind of mapping is achieved by performing some sort of permutation on the plaintext letters. This technique is referred to as a transposition cipher.

3.2 Transposition Cipher

The simplest such cipher is the **rail fence** technique, in which the plaintext is written down as a sequence of diagonals and then read off as a sequence of rows. A more complex scheme is to write the message in a rectangle, row by row, and read the message off, column by column, but permute the order of the columns. The order of the columns then becomes the key to the algorithm.

A way to make the encryption stronger is to use double transposition instead of a single one.

The Playfair algorithm is based on the use of a 5×5 matrix of letters constructed using a keyword. Here is an example, solved by Lord Peter Wimsey in Dorothy Sayers's *Have His Carcase*:⁴

M	O	N	A	R
C	H	Y	B	D
E	F	G	I/J	K
L	P	Q	S	T
U	V	W	X	Z

In this case, the keyword is *monarchy*. The matrix is constructed by filling in the letters of the keyword (minus duplicates) from left to right and from top to bottom, and then filling in the remainder of the matrix with the remaining letters in alphabetic order. The letters I and J count as one letter. Plaintext is encrypted two letters at a time, according to the following rules:

1. Repeating plaintext letters that are in the same pair are separated with a filler letter, such as x, so that balloon would be treated as ba lx lo on.
2. Two plaintext letters that fall in the same row of the matrix are each replaced by the letter to the right, with the first element of the row circularly following the last. For example, ar is encrypted as RM.
3. Two plaintext letters that fall in the same column are each replaced by the letter beneath, with the top element of the column circularly following the last. For example, mu is encrypted as CM.
4. Otherwise, each plaintext letter in a pair is replaced by the letter that lies in its own row and the column occupied by the other plaintext letter. Thus, hs becomes BP and ea becomes IM (or JM, as the encipherer wishes).

Figure 4: An example of implementing Playfair Cipher

3.3 Rotor Machines

This essentially generates a large amount of polyalphabetic substitution ciphers with $26 * 26 * 26 = 17,576$ different substitution alphabets (for 3-motor machine Figure 5) used before the system repeats. Making a 5-motor machine equivalent to Vigenere cipher with a key length of 11,881,376.

With each stroke the first motor rotates one step changing the mapping of alphabets in the first motor itself, subsequent motors rotate one step on a complete rotation of the previous motor.

The technique turns out formidable be solved by using frequency analysis.

3.4 FEISTEL CIPHER STRUCTURE

The left-hand side of Figure 6 depicts the encryption structure proposed by Feistel. The inputs to the encryption algorithm are a plaintext block of length $2w$ bits and a key K . The plaintext block is divided into two halves, LE_0 and RE_0 . The two halves of the data pass through n rounds of processing and then combine to produce the ciphertext block. Each round i has as inputs LE_{i-1} and

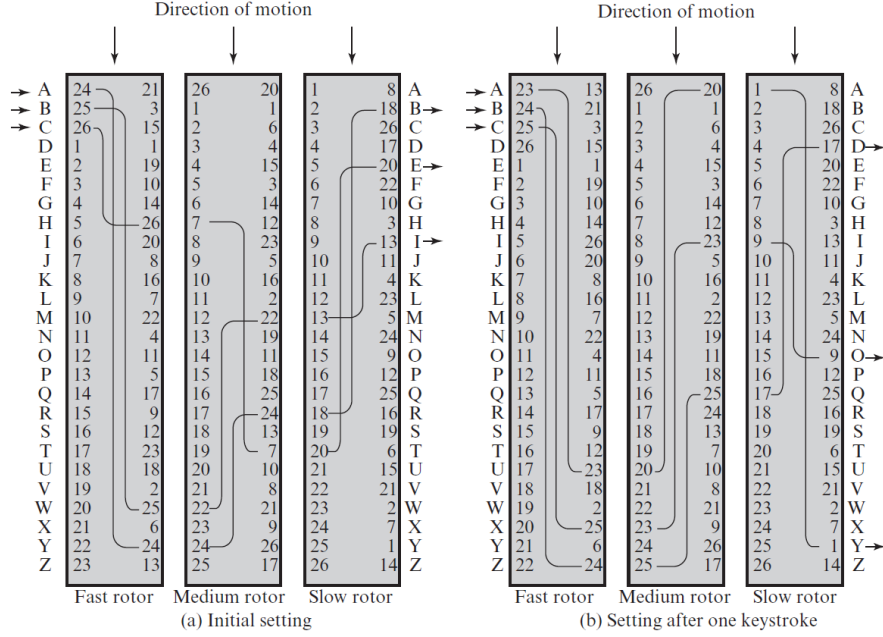

Figure 5: Three-Rotor Machine with Wiring Represented by Numbered Contacts [6]

RE_{i-1} derived from the previous round, as well as a subkey K_i derived from the overall K . In general, the subkeys K_i are different from K and from each other. In Figure 6, 16 rounds are used, although any number of rounds could be implemented. All rounds have the same structure. A substitution is performed on the left half of the data. This is done by applying a round function F to the right half of the data and then taking the exclusive-OR of the output of that function and the left half of the data. The round function has the same general structure for each round but is parameterized by the round subkey K_i . Another way to express this is to say that F is a function of right-half block of w bits and a subkey of y bits, which produces an output value of length w bits: $F(RE_i, K_{i+1})$. Following this substitution, a permutation is performed that consists of the interchange of the two halves of the data. This structure is a particular form of the substitution-permutation network (SPN) proposed by Shannon.

3.5 The Data Encryption Standard

The overall scheme for DES encryption is illustrated in Figure 7. As with any encryption scheme, there are two inputs to the encryption function: the plaintext to be encrypted and the key. In this case, the plaintext must be 64 bits in length and the key is 56 bits in length.

Looking at the left-hand side of the figure, we can see that the processing of the plaintext proceeds in three phases. First, the 64-bit plaintext passes through an initial permutation (IP) that rearranges the bits to produce the permuted input. This is followed by a phase consisting of sixteen rounds of the same function, which involves both permutation and substitution functions. The output of the last (sixteenth) round consists of 64 bits that are a function of the input plaintext and the key. The left and right halves of the output are swapped to produce the preoutput. Finally, the preoutput is passed through a permutation [IP^{-1}] that is the inverse of the initial permutation function, to produce the 64-bit ciphertext.

With the exception of the initial and final permutations, DES has the exact structure of a Feistel cipher, as shown in Figure 6. The right-hand portion of Figure 7 shows the way in which the 56-bit key is used. Initially, the key is passed through a permutation function. Then, for each of the sixteen rounds, a subkey (K_i) is produced by the combination of a left circular shift and a permutation. The permutation function is the same for each round, but a different subkey is produced because of the repeated shifts of the key bits.

The concept of Advanced Encryption Standard will be dealt later in depth, according to PoA.

4 Asymmetric Key Cryptography

Figure 8 outlines the working of Asymmetric Key/ Public Key Cryptosystems.

4.1 Terminology

Asymmetric Keys Two related keys, a public key and a private key, that are used to perform complementary operations, such as encryption and decryption or signature generation and signature verification.

Public Key Certificate A digital document issued and digitally signed by the private key of a Certification Authority that binds the name of a subscriber to a public key. The certificate indicates that the subscriber identified in the certificate has sole control and access to the corresponding private key.

Public Key Infrastructure (PKI) A set of policies, processes, server platforms, software and workstations used for the purpose of administering certificates and public-private key pairs, including the ability to issue, maintain, and revoke public key certificates.

In case A prepares a message to B and encrypts it using A's private key then B can decrypt the message using A's public key. Because the message was encrypted using A's private key, only A could have prepared the message. Therefore, the entire encrypted message serves as a **digital signature**. In

addition, it is impossible to alter the message without access to A's private key, so the message is authenticated both in terms of source and in terms of data integrity.
